Python Track

DS Basics 2 - Sets and Dictionaries

Lecture Flow

- **Sets**

- **Dictionaries**

Sets

What Is Set?

Set

- A set is a built-in data type in Python that represents an unordered, unindexed collection of unique and unchangeable elements.

Initialization

- set() constructor

```python
empty_set = set() #empty set
numbers_set = set([1, 2, 3, 4, 5]) # Converts any iterable to a set
```

- Curly braces { }

```python
numbers_set = {1, 2, 3, 4, 5}  # Creates a set with elements
empty_set = {} # Valid ?
```

What Data Type Can Set Store?

- Sets can store elements of various data types, as long as those elements are immutable.
- Integers, Floats, Strings,Tuples, and Booleans.

```python
my_set = {1, 2.5, "apple", (1, 2, 3), True}

invalid_set = {1, 2, [3, 4]} # Why invalid?
```

Basics of how Set works

- Sets in Python use a hash table to store elements, which is like a large storage box with many compartments (buckets).
- When you add an element to the set, a special function (hash function) converts the element into a unique code that determines which bucket the element goes into.
- When you check if an element is in the set (lookup), the hash function is used again to find the compartment where that element should be.

Basics of how Set works
Access Elements

- You cannot access items in a set by referring to an index or a key.
- To check if an item is in a set, you use the **in** operator.

```python
my_set = {1, 2, 3, 4, 5}
if 3 in my_set:
    #code
```

- You can iterate through all items in a set using a **for-in** loop

```python
for item in my_set:
    #code
```

Add And Remove Elements

- The add() method is used to add a single element to a set.
- The update() method is used to add multiple elements using iterables (lists, tuples)
- The union() method Return a set containing the union of sets

```python
my_set1 = set()
My_set2 = {10,11,12}

my_set1.add(1)
my_set1.add(2)
my_set1.add(3)

print(my_set1) # {1,2,3}
```

```python
my_set1.update([3, 4, 5])
print(my_set1) # {1,2,3,4,5}

my_set3 = my_set1.union(my_set2)
print(my_set3) # {1,2,3,4,5,10,11,12}
```

Add And Remove Elements

- The clear() method removes all the elements from the set.
- The remove() and discard() methods remove the specified item.
  - If the item does not exist, `remove()` raises a `KeyError`, while `discard()` does not raise an error.
- pop() method removes and returns a **random** element from the set.

```
my_set = {1,2,3,4,5}
my_set.remove(2) # ?
my_set.remove(6) # ?
my_set.discard(2) # ?
my_set.discard(6) # ?
```

```
my_set.pop() # ?
my_set.clear() # ?
```

What Are Valid And Invalid Operators In Set?

Valid Operators

```
set1 = {1, 2, 3}     set2 = {3, 4, 5}
```

- **Union (|)**
  ```
  union_set = set1 | set2
  #returns {1, 2, 3, 4, 5}
  ```

- **Intersection (&)**
  ```
  intersection_set = set1 & set2
  #returns {3}
  ```

- **Difference (-)**
  ```
  difference_set = set1 - set2
  #returns {1, 2}
  ```

Valid Operators

Symmetric Difference (^)
```
symmetric_difference_set = set1 ^ set2
#returns {1, 2, 4, 5}
```

Subset (<=) and Superset (>=)
```
is_subset = set1 <= set2  #returns False
is_superset = set1 >= set2 #returns False
```

Equality(==)
```
set1 == set2  #returns False
```

Invalid Operators

- **Concatenation** (**+**)
- **Multiplication** (*****)
- **Indexing** ([ ]) **and** Slicing ([:])

Set Comprehension

- A set comprehension in Python is a concise way to create a set using curly braces {} .

```python
Set_name = {expression for item in iterable if condition}

squares_set = {x**2 for x in range(10)}
squares_set = {x**2 for x in range(10) if x % 2}
```

Set Methods

Method	Description
add()	Adds an element to the set
clear()	Removes all the elements from the set
copy()	Returns a copy of the set
difference()	Returns a set containing the difference between two or more sets
difference_update()	Removes the items in this set that are also included in another, specified set
discard()	Remove the specified item
intersection()	Returns a set, that is the intersection of two other sets
intersection_update()	Removes the items in this set that are not present in other, specified set(s)
isdisjoint()	Returns whether two sets have a intersection or not
issubset()	Returns whether another set contains this set or not
issuperset()	Returns whether this set contains another set or not
pop()	Removes an element from the set
remove()	Removes the specified element
symmetric_difference()	Returns a set with the symmetric differences of two sets
symmetric_difference_update()	inserts the symmetric differences from this set and another
union()	Return a set containing the union of sets
update()	Update the set with the union of this set and others

Advantage of sets

1. Uniqueness of Elements
2. Fast Membership Testing
3. Mathematical Set Operations

Frozenset

- a frozenset is an immutable and hashable version of a set.

```python
frozenset1 = frozenset([1, 2, 3])
frozenset2 = frozenset([3, 4, 5])

frozenset1.add(4) # possible?
union_frozenset = frozenset1 | frozenset2 # possible?
intersection_frozenset = frozenset1 & frozenset2 # possible?
```

Exercises

1. [Contains Duplicate - Leetcode](#)
2. [Union of two arrays | Practice | GeeksforGeeks](#)

Dictionaries

What Is Dictionary?

Dictionary

- A dictionary is an ordered (as of Python version 3.7) collection of key-value pairs, where each key must be unique and is associated with a specific value.
- They are also mutable and dynamic data structures

Initialization

- dict() constructor

```python
empty_dictionary = dict() #empty dictionary
dictionary_from_list = dict([('name', 'John'),('age', 30),
('city','New York')])
```

- Curly braces { }

```python
dictionary = {'name': 'John', 'age': 30, 'city': 'New York'}
```

- Dictionary comprehension
```python
sqr_dict = {num: num**2 for num in range(1, 11)}
```

What Can Be Used as Keys in Python Dictionaries?

Valid Data Types for Dictionary Keys

- Dictionary keys must be immutable data types to maintain data integrity.
- Integers, Floats, Strings,Tuples and Booleans.

```python
my_dictionary = {(1, 2): "Tuple Key", False: "Key"}
my_dictionary = {[1, 2]: "List Key"} #why invalid?
```

Common Operations In Dictionary

- **Access**

```python
age = my_dict["age"]
age = my_dict.get("age", 0) #why safe?
```

- **Add or Update**

```python
my_dict["age"] = 20
my_dict["age"] = my_dict.get("age",0) + 10
```

- **Removing Key**

```python
value = my_dict.pop("age")
```

Common Operations In Dictionary

- **Checking if the key exist**

    ```python
    if "age" in my_dict
    ```

- **Iterating**

    - Through Keys:
        ```python
        for key in my_dict:
        ```
    - Through key-value pairs:
        ```python
        for key, value in my_dict.items():
        ```
    - Through values:
        ```python
        for value in my_dict.values():
        ```

Dictionary Copying

- **Assignment Operator (=):**

```python
my_dict1 = {'key1': 'value1', 'key2': 'value2'}
my_dict2 = my_dict1
my_dict2['key1'] = 'value3'
print(my_dict1) # Output?
```

- **Note:** In Python, when you use the assignment operator (=) to assign any object to another variable, both variables reference the same underlying iterable in memory. modifications made to the iterable through one variable will be visible when accessing the iterable through the other variable, and vice versa.

Shallow Copy

- A shallow copy creates a new dictionary but does not create new copies of the objects inside the dictionary.
- Changes made to mutable objects (like lists) within the original dictionary will affect the corresponding objects in the copied dictionary, and vice versa.

Shallow Copy

- Shallow copy is performed using methods like
    - copy(),
    - dict(), or
    - dictionary unpacking ({**original_dict}).

Shallow Copy

```python
original_dict = {'key1': ['value1'], 'key2': 'value2'}
shallow_copied_dict = original_dict.copy()

original_dict['key1'].append('value3')
original_dict['key2'] = 'value4'

print(shallow_copied_dict)  # Output?

original_dict['key1'] = [1, 2, 3]

print(shallow_copied_dict)  # Output?
```

Deep Copy

- A deep copy creates a new dictionary and recursively creates new copies of all objects inside the original dictionary, including nested objects.
- Changes made to mutable objects within the original dictionary will not affect the corresponding objects in the copied dictionary, and vice versa.

Deep Copy

- Deep copy is performed using the deepcopy function from the copy module.

Deep Copy

```python
import copy

original_dict = {'key1': ['value1'], 'key2': 'value2'}
deep_copied_dict = copy.deepcopy(original_dict)

original_dict['key1'].append('value3')

print(deep_copied_dict)  # Output?
```

Dictionary Methods

Method	Description
clear()	Removes all the elements from the dictionary
copy()	Returns a copy of the dictionary
fromkeys()	Returns a dictionary with the specified keys and value
get()	Returns the value of the specified key
items()	Returns a list containing a tuple for each key value pair
keys()	Returns a list containing the dictionary's keys
pop()	Removes the element with the specified key
popitem()	Removes the last inserted key-value pair
setdefault()	Returns the value of the specified key. If the key does not exist: insert the key, with the specified value
update()	Updates the dictionary with the specified key-value pairs
values()	Returns a list of all the values in the dictionary

Advantage of Dictionaries

1. Efficient Data Retrieval
2. Fast Membership Testing
3. Dynamic Size

Hash Collisions in Sets and Dictionaries

- A **hash collision** occurs when two distinct objects (keys or set elements) have the same hash value.
- This can happen because hash values are finite, so multiple objects can have the same hash code.
Exercises

1. Missing Number - LeetCode
